## Abstract

We report the realization of a Pancharatnam-Berry phase optical element [Z. Bomzon, G. Biener, V. Kleiner, and E. Hasman, *Opt. Lett.* **27**, 1141 (2002)] for wavefront shaping working in the visible spectral domain, based on patterned liquid crystal technology. This device generates helical modes of visible light with the possibility of electro-optically switching between opposite helicities by controlling the handedness of the input circular polarization. By cascading this approach, fast switching among multiple wavefront helicities can be achieved, with potential applications to multi-state optical information encoding. The approach demonstrated here can be generalized to other polarization-controlled devices for wavefront shaping, such as switchable lenses, beam-splitters, and holographic elements.

When the polarization of an electromagnetic wave undergoes a continuous sequence of transformations following a closed path in the space of polarization states (e.g., the Poincaré sphere), the wave acquires a phase shift, known as Pancharatnam-Berry phase, that is determined only by the geometry of the polarization path.<sup>1,2</sup> By the same principle, if a wave is subjected to transversely inhomogeneous polarization transformations with a homogeneous initial and final polarization state, the associated inhomogeneous geometrical phases will induce an overall wavefront reshaping. This approach to wavefront shaping is fundamentally different from the usual optical-path-length approaches of standard lenses, curved mirrors, and gradient-index (GRIN) elements. It is also conceptually different from holographic approaches, although the two are related, as we will discuss further below. The realization of so-called *Pancharatnam-Berry phase optical elements* (PBOE) for wavefront shaping has been proposed only recently,<sup>3,4</sup> and it has been experimentally demonstrated only in the mid-infrared domain, using subwavelengths inhomogeneous gratings to manipulate the polarization.<sup>4,5,6,7</sup> An additional general feature of PBOE's is that they are *polarization-controlled*, i.e. different input polarizations will give rise to different wavefront shaping in the same PBOE element. Since the polarization can be electro-optically switched at a high rate, PBOE's allow a very fast control of the generated wavefront. This polarization multiplexing is limited to a finite set of predefined wavefronts, so PBOE's cannot compete with spatial light modulators in terms of flexibility, but they will be much faster and cheaper.

To be more specific, let us consider a PBOE made as a single (uniaxial) birefringent plate having a homogeneous phase retardation of  $\pi$  (half-wave PBOE) for light propagation in the longitudinal  $z$  direction but a transversely inhomogeneous optical axis  $\mathbf{n}(x, y)$ , lying in the  $xy$  plane. To analyze the effect of this element on the optical field, it is convenient to adopt the Jones formalism. Let  $\alpha(x, y)$  be the angle between  $\mathbf{n}(x, y)$  and a fixed axis  $x$ . The Jones matrix  $\mathbf{M}$  to be applied on the field at each transverse position  $x, y$  is the following:

$$\mathbf{M} = \mathbf{R}(-\alpha) \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \mathbf{R}(\alpha) = \begin{pmatrix} \cos 2\alpha & \sin 2\alpha \\ \sin 2\alpha & -\cos 2\alpha \end{pmatrix}, \quad (1)$$

where  $\mathbf{R}(\alpha)$  is the two-dimensional rotation matrix by angle  $\alpha$ . An input left-circular polarized plane wave, described by the Jones electric-field vector  $\mathbf{E}_{\text{in}} = E_0 \times [1, i]$ , will be

transformed by this element into the following field (up to an overall phase):

$$\mathbf{E}_{\text{out}} = \mathbf{M} \cdot \mathbf{E}_{\text{in}} = E_0 e^{i2\alpha(x,y)} \begin{bmatrix} 1 \\ -i \end{bmatrix}. \quad (2)$$

It is seen that the output wave is uniformly right-circular polarized, but its wavefront has acquired a nonuniform phase retardation  $\Delta\Phi(x, y) = 2\alpha(x, y)$ . If the input light is right-circular polarized, it is easy to verify that the wavefront is the conjugate one, i.e.  $\Delta\Phi(x, y) = -2\alpha(x, y)$ .

To appreciate the possible applications of these devices, consider, for example, a half-wave PBOE having a polarization-grating geometry as that shown in Fig. 1a. This device will function as a circular-polarizing beam-splitter or as polarization-controlled optical switch.<sup>6</sup> A PBOE lens can instead be obtained with an optical axis geometry given by  $\alpha \propto r^2$ , where  $r$  is the radial coordinate in the  $xy$  plane, as that shown in Fig. 1b. This element will be focusing or defocusing, depending on the input circular polarization handedness.<sup>3,7</sup>

Let us consider now a PBOE geometry given by  $\alpha = q\varphi + \alpha_0$ , where  $\varphi$  is the azimuthal angle in the  $xy$  plane, and  $q$  and  $\alpha_0$  are two constants. We further assume that  $q$  is an integer or a semi-integer, so that the optical axis does not have discontinuity lines in the plate, but only a defect in the center. We will call these devices “ $q$ -plates”. Figures 1c and 1d show examples of these devices for  $q = 1/2$  and  $q = 1$ , respectively. These  $q$ -plates give rise to a wavefront modulation given by  $\Delta\Phi = \pm 2q\varphi$ , with a sign depending on the input circular polarization handedness, i.e. they generate helical wavefronts of order  $\pm 2q$ .<sup>8,9</sup> Thus far,  $q$ -plates have been demonstrated only for the mid-infrared wavelength of  $10.6 \mu\text{m}$ , based on the subwavelength gratings technology.<sup>5,10</sup>

We manufactured  $q = 1$  plates working at the visible wavelength  $\lambda = 633 \text{ nm}$  based on the patterned liquid crystal (LC) technology (see, e.g., Refs. 11,12 and references therein). Nematic LC planar cells were prepared with a thickness (about  $1 \mu\text{m}$ ) and a material (E63 from Merck, Darmstadt, Germany) chosen so as to obtain a birefringence retardation of approximately a half wave. Before cell assembly, one of the inner surfaces of the two containing glasses of the cell was pressed against a piece of fabric kept in continuous rotation. This “circular rubbing” procedure leads to a surface easy axis (i.e. the preferred orientation of LC molecules) having the desired  $q = 1$  circular-symmetric geometry, as that shown in Fig. 1d. The other glass was left unrubbed, for degenerate planar alignment. To ensure good LC alignment, the cell was heated above the clearing point and then cooled slowly, keeping the

rubbed surface slightly colder than the unrubbed one. In this way, nematic order nucleated on the rubbed surface and then extended to the whole cell. Some cells were prepared with a polyimide coating for planar alignment, others with bare glass, with comparable results (although they required different rubbing pressures and lengths). A photograph of a LC  $q$ -plate held between crossed polarizers is shown in Fig. 2a.

To test the optical effect of a  $q$ -plate, a circularly-polarized He-Ne laser beam having a TEM<sub>00</sub> transverse mode and a beam-waist radius of about 1 mm was sent through it, taking care of aligning the beam axis on the  $q$ -plate center. The intensity profile of the output beam, shown in Fig. 2b, has the “doughnut” shape expected for a helical mode. However, a complete test must be based on measuring the beam wavefront shape, rather than its intensity profile. To this purpose, we inserted the  $q$ -plate in the signal arm of a Mach-Zender interferometer based on the same He-Ne laser source. The input circular-polarization handedness was selected by properly rotating a quarter-wave plate. The beam emerging from the  $q$ -plate was sent through another quarter-wave plate and a linear polarizer arranged for transmitting the polarization handedness opposite to the initial one, so as to eliminate any residual unchanged circular polarization (this step would be unnecessary for an exact half-wave retardation of the  $q$ -plate). The final interference pattern generated after superposition with the reference was formed directly on the sensing area of a CCD camera. We used two reference wavefront geometries: (i) plane-tilted, for which an order-2 helical wavefront will give rise to a double disclination defect in a otherwise regular straight-line fringe pattern; (ii) spherical, for which the helical wavefront will give rise to a double spiral fringe pattern. Figures 2c-f show the interference patterns we obtained for one of our cells in these two geometries, respectively for a left-circular (panels c and e) and right-circular (panels d and f) input polarization. These results confirm that the wavefront of the light emerging from our  $q$ -plate is indeed helical of order  $\pm 2$ , as expected, with the  $\pm$  sign determined by the input polarization handedness.

This polarization-based control of the generated helical wavefront is a good example of the possible advantages of the PBOE approach to wavefront shaping. Indeed, all other existing approaches to helical mode generation (i.e. cylindrical lenses, spiral phase plates, and holographic methods) have an essentially fixed output. Of course, by introducing a suitable spatial light modulator, dynamical control becomes possible, but only at relatively low switching rates. In our approach, a simple electro-optical control of the input polariza-

tion allows switching of the generated helical mode at very high rate. By cascading several  $q$ -plates in series with suitable electro-optic devices in between, as shown in Fig. 3, one can obtain fast switching among several different helical orders. This could be very useful if helical modes are to be used in multi-state optical information encoding, as recently proposed for classical communication<sup>13</sup> and for quantum communication and computation.<sup>14,15</sup>

Although in our proof-of-principle demonstration reported here we used a method for patterning our LC cell that works only for circular-symmetric geometries (as in the  $q = 1$  plate), LC cell patterning has the potential for obtaining any desired PBOE geometry. Different approaches, such as micro-rubbing,<sup>11</sup> masked or holographic photo-alignment,<sup>16,17</sup> and silicon-oxide evaporated coatings,<sup>18</sup> are all suitable.

Finally, we note that the PBOE principle is strictly related to the so-called *polarization holography* (PH), in which the holographic material records the information contained in the optical polarization.<sup>19</sup> Typically, in PH one needs a light-sensitive polymer that can align its molecular chains parallel or perpendicular to the polarization direction.<sup>20</sup> In order to memorize a given wavefront in a PH hologram, one must superimpose the wave carrying that wavefront with a plane-wave reference, taking care that both waves are circularly polarized, with opposite handedness. The resulting interference field will have uniform intensity and it will be everywhere linearly polarized, but it will have a nonuniform polarization orientation which will be imprinted in the hologram. When illuminated with a plane wave, this hologram will reconstruct the recorded wavefront, or its conjugate, at its  $\pm 1$  diffraction orders. However, if the hologram is “developed” into a inhomogeneous birefringent plate having half-wave retardation (for example by using the hologram as a “command” surface of a LC cell, or if the hologram itself has sufficient birefringence), the zero diffraction order will vanish identically and the hologram becomes a PBOE device generating a single optical output with the recorded wavefront, or its conjugate, when illuminated with a circularly polarized plane wave.

In conclusion, we have demonstrated a Pancharatnam-Berry phase optical element working in the visible domain, based on patterned liquid crystal technology. This device can be used for generating fast switchable helical modes, with potential applications to optical information encoding. Some plausible strategies for generalizing our approach have been discussed.
